

The A/B test results (ANOVA: $F = 21.95$, $p = 0.0000$) confirmed that the difference between the promotions was significant, and the choice of promotion directly impacted revenue.

The **first promotion was the sales leader** (average \$58.1 thousand), the **third was slightly behind** (55.4 thousand), while the **second was significantly worse** (47.3 thousand) and failed in all market segments.

But digging deeper, an interesting detail emerges: in large markets, **the third promotion performed better** (77.2 thousand), slightly outperforming the first (75.2 thousand). In medium-sized markets, the first promotion clearly led (47.7 thousand), followed by the third (45.5 thousand), and the second again lagged behind (39.1 thousand). In small markets, the first and third promotions are practically identical: 60.2 and 59.5 thousand, while the second is slightly lower at 50.8 thousand.

Moreover, **store age had no effect**: the correlations with sales are close to zero (-0.14, 0.07, and -0.05 for each promotion).

Conclusion: the first and third promotions should definitely be continued, but with a reference to the point scale. The second promotion, however, should either be completely redesigned or eliminated. For greater certainty, you can also compare all the promotions in pairs (for example, using a Tukey test), but the overall picture is clear.
